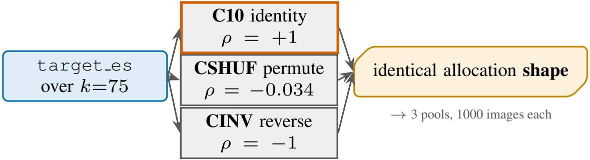
## **EXP T2** — the falsification arms

**[scope: signal+data]**

*A/B/C could not separate* concentration *from* targeting. *With the allocation shape held exactly fixed, does the* direction *of the uncertainty signal change trained accuracy at all?*

### SETUP



the shape is not *approximately* equal — all four allocation keys reproduce C1's committed cell at **exact 5-dp equality** (`alloc_entropy_norm` **0.78644**, `tv_from_uniform` **0.49253**, and two more), so the arms differ in the signal's *direction* and in nothing else — which A/B/C structurally could not do.

### MEASUREMENT

$|\Delta|$ as a multiple of $\hat{\sigma}$, for every gap × architecture × endpoint:

| | SI/C | v2/C | SI/N | v2/N |
|---|---|---|---|---|
| CSHUF–C10 | 0.55 | 0.83 | 0.62 | 0.66 |
| CINV–C10 | 0.31 | 0.72 | 1.20 | 1.40 |
| CINV–CSHUF | 0.86 | 0.11 | 1.82 | 0.74 |

every cell is below its bar of $2\hat{\sigma}$; the largest gap anywhere is **0.005007** ($1.82\,\hat{\sigma}$)

### OUTCOME

**12 of 12** cells WITHIN NOISE, at a bar **3.24× tighter** than A/B/C's ($2\hat{\sigma} = 0.005533$ vs $0.017933$ on SINet).

Reported though not significant: **C10 — the real signal — has the highest arm mean in none of the four cells**, and CINV, the maximally anti-targeted arm, has it in three.

**real, destroyed and reversed targeting are indistinguishable**
the signal's direction carries no accuracy-relevant information at this sensitivity
